1 Introduction

In this paper we shall prove two fundamental theorems on the topological uniqueness of certain surfaces in R^3 . The first of these theorems, which will depend on the second theorem, shows that a properly embedded minimal surface in R^3 with one end is unknotted. More precisely,

Theorem 1.1 *Two properly embedded one-ended minimal surfaces in R^3 of the same genus are ambiently isotopic¹.*

Theorem 1.1 was conjectured by Frohman [10] who proved it in the case that the surfaces are triply-periodic. Earlier Meeks [18] proved the theorem in the case of finite genus and a recent example of Hoffman, Karcher and Wei [15]. In this case the only known examples are the plane and the helicoid. However, the collection of properly embedded minimal surfaces of infinite genus and one end is extremely rich. One reason for this is that most classical examples of these surfaces are doubly-periodic (i.e., they are invariant under translation in two independent directions) and

†The research described in this paper was supported by research grant DE-FG02-86ER250125 of the Applied Mathematical Science subprogram of the Office of Energy Research, U.S. Department of Energy, and National Science Foundation grant DMS-8900285.

¹Two surfaces in R^3 are ambiently isotopic if and only if there exists a one-parameter family of diffeomorphisms of R^3 taking one surface to the other.

in this case, a result of Callahan, Hoffman, and Meeks (Corollary 2 in [3]) states that the surface has one end and infinite genus, when it is not a plane. This result and Theorem 1.1 have the following corollary.

Corollary 1.1 *Any two properly embedded nonplanar minimal surfaces in \mathbb{R}^3 that are invariant under at least two linearly independent translations are ambiently isotopic.*

Essential in understanding the uniqueness theorems in this paper is the concept of a Heegaard surface in a noncompact three-manifold, which generalizes the usual notion of a Heegaard surface M in a closed three-manifold N^3 . Recall that M is called a *Heegaard surface* if it separates N^3 into two genus- g handlebodies where g is the genus of M . (A handlebody of genus g is also frequently referred to in the literature as a solid g -holed torus, a g -holed doughnut or a pretzel of genus g . Every closed three-manifold N^3 contains a Heegaard surface, so N^3 can be constructed by glueing two handlebodies together along their boundary (see [13] for details)).

Heegaard surfaces in N^3 , which thereby yield “Heegaard splittings” of N^3 into handlebodies, play a fundamental role in classification questions in three dimensional topology. We refer the interested reader to [1, 2, 4, 10, 9, 11, 13, 17, 18, 24, 30] for some of the theorems on Heegaard surfaces and the application of these theorems to geometry.

Noncompact three-manifolds such as \mathbb{R}^3 fail to have compact Heegaard surfaces. However, there is a natural notion of Heegaard surface for these manifolds where the surface is allowed to be noncompact. (See Section 2 for the precise definition.) We say that a properly embedded surface M is a *Heegaard surface* in \mathbb{R}^3 if the closures of each of the two components of $\mathbb{R}^3 - M$ are handlebodies². We will show that these handlebodies are each diffeomorphic to the three-manifold constructed as follows. Attach g trivial one-handles to the closed lower halfspace H in \mathbb{R}^3 where g is the genus of M , possibly infinite. When $g = \infty$, this attaching of handles on H can be performed on neighborhoods of the integer points on the x -axis contained in ∂H to obtain a one-periodic Heegaard surface in \mathbb{R}^3 (see Figure 1). Note that this implies that a Heegaard surface in \mathbb{R}^3 has *one* end.

²A three-manifold with boundary is a *handlebody* if it is homeomorphic to a closed regular neighborhood of a properly embedded one-dimensional CW-complex in \mathbb{R}^3 .

Figure 1:

Our second main theorem is

Theorem 1.2 *Heegaard surfaces of the same genus in \mathbb{R}^3 are ambiently isotopic. Equivalently, given two diffeomorphic Heegaard surfaces in \mathbb{R}^3 , there exists a diffeomorphism of \mathbb{R}^3 that takes one surface to the other surface.*

Theorem 1.2 will be proved at the end of Section 2.

We will prove in Section 3 that a properly embedded one-ended minimal surface in \mathbb{R}^3 is a Heegaard surface. This result, together with Theorem 1.2, will prove Theorem 1.1.

The one-skeletons of different triangulations of \mathbb{R}^3 are not in general homeomorphic. However, since the boundary surfaces of their regular neighborhoods are Heegaard surfaces of infinite genus, Theorem 1.2 yields

Corollary 1.2 *The regular neighborhoods of the one-skeletons of any two triangulations of \mathbb{R}^3 are ambiently isotopic.*

Acknowledgements.

We would like to thank Bob Edwards for his interest in Theorems 1.1 and 1.2, as well as useful conversations related to their proof. We are also grateful to Jim Hoffman who produced the computer graphics images of Scherk's singly-periodic and doubly-periodic minimal surfaces and Schwarz's Primitive surface. Computer graphics images of these surfaces appear in Images 1, 2, and 3 in Section 4. The production of these images were made with the facilities of GANG, the Center for Geometry, Analysis, Numerics and Graphics at the University of Massachusetts.

2 Topological uniqueness of one-ended Heegaard surfaces

There is a subtle point related to the proof of Theorem 1.2 that we would like to point out to the reader. It follows immediately from the work of Frohman in [10] that a Heegaard surface of infinite genus in \mathbb{R}^3 contains an infinite number of disjoint trivial handles. (See Figure 3 for a picture of a trivial handle.) The main difficulty in proving Theorem 1.2 is to show that such a collection of disjoint trivial handles can be chosen to be a proper subset of \mathbb{R}^3 . This subtle properness problem will be handled through the technical application of hollow Heegaard splitting to be defined shortly.

Before proceeding to the proof of Theorem 1.2, we develop some basic notation, definitions and topological constructions that will be used in our analysis of Heegaard splittings of \mathbb{R}^3 .

Let M and N be manifolds with boundary. A continuous map $f: M \rightarrow N$ is called *proper* if

1. For every compact set $K \subset N$, the set $f^{-1}(K)$ is compact, and
2. $f(\partial M) = f(M) \cap \partial N$.

We require all submanifolds to be topologically locally flat. We use the notation \overline{A} to denote the closure of a set A .

We seek to generalize the notions of handlebody and compressionbody (to be defined) to include noncompact objects. A space B is a *handlebody* if there exists a one-dimensional CW-complex X that is properly embedded in \mathbb{R}^3 and a closed regular neighborhood, $N(X)$, that is homeomorphic to B . The genus of the handlebody B is the genus of ∂B . If B is compact, then, up to homeomorphism, B is classified by its genus. Let M and N be three-manifolds with boundary. The *boundary connect sum* of M and N is the three-manifold $M \# N$ obtained by identifying a disk D_1 in the boundary of M with a disk D_2 in the boundary of N .

A compressionbody is a space that can be constructed as follows. Let F be a compact orientable surface with or without boundary. If F has genus zero, we require that ∂F be nonempty. Let I denote the unit interval $[0, 1]$. Let B be a handlebody as above and let D_1 be a disk in ∂B . Let D_2 be a disk in $F \times \{0\}$. The space $H = B \# (F \times I)$, where we take the sum along D_1 and D_2 , is a *compressionbody*. The surface $\overline{(\partial B - D_1)} \cup \overline{(\partial F \times \{0\} - D_2)}$ will be called *the distinguished surface* of H . We can more generally define a *compressionbody* to be the boundary connect sum of

a handlebody with a finite number of $F \times I$ where the surfaces F are compact, and if some F has genus zero then we require that F have boundary. The restriction that the surfaces of genus 0 have boundary is to guarantee that compressionbodies have trivial second homotopy group.

Let X be a topological space. If K is a compact subset of X , then define $n(K)$ to be the number of connected components of $X - K$ that have noncompact closure. The number of ends of X , which we denote $e(X)$, is the supremum of $n(K)$ taken over the compact subsets of X . It is easy to check that \mathbb{R}^n has two ends for $n = 1$ and one end for $n > 1$. The number of ends of a compressionbody H is equal to the number of ends of its distinguished surface. The number of ends of a topological space can be computed as the rank of the 0-dimensional term of a cohomology theory [27]. Hence there is an inequality relating the number of ends of a space X to the number of ends of a pair of nice subspaces X_1, X_2 and their intersection $X_1 \cap X_2$, such that $X = X_1 \cup X_2$, that comes from a Mayer-Vietoris sequence. Specifically, $e(X) \geq e(X_1) + e(X_2) - e(X_1 \cap X_2)$.

A simple closed curve κ in a surface F is *essential* if κ is not the boundary of a disk embedded in F . A *meridian disk* D for a handlebody B is a properly embedded disk so that ∂D is an essential simple closed curve in ∂B . A *system of meridian disks* is a disjoint union of disks D_i that has been properly embedded in B so that each disk in the family is a meridian disk. Let B be a handlebody of infinite genus having one end. A *standardizing sequence for B* is a system of meridian disks $\{D_i\}$ for B where the index i ranges over the positive integers, and the disk D_i cuts B into a handlebody of genus i that contains all D_j with $j < i$ and an unbounded component. (See Figure 2.) Every handlebody B with one end and infinite genus has a standardizing sequence. From this it follows that up to homeomorphism there is only one handlebody of infinite genus having one end.

$$D_1 \qquad D_2 \qquad D_3$$

Figure 2:

Definition 2.1 *Let M be a three-manifold and let F_1 and F_2 be compact surfaces in ∂M so that $\partial M = F_1 \cup F_2$ and $F_1 \cap F_2 = \partial F_1 = \partial F_2$. A hollow Heegaard splitting of (M, F_1, F_2) is a pair (H_1, H_2) of compressionbodies H_1 and H_2 embedded in M so that:*

1. $H_1 \cup H_2 = M$;
2. $F = H_1 \cap H_2$ is the distinguished surface of both H_1 and H_2 ;
3. F is properly embedded in M ;
4. $\partial F = F_1 \cap F_2$;
5. $F_i \subset \partial H_i$.

We call F the splitting surface associated to the hollow Heegaard splitting. If H'_1 and H'_2 are also hollow handlebodies, then we say that (H_1, H_2) and (H'_1, H'_2) of (M, F_1, F_2) are topologically equivalent if there exists a homeomorphism $h: M \rightarrow M$ so that $h(H_1) = H'_1$ and $h(H_2) = H'_2$.

From our remarks about the ends of topological spaces, it can be seen that if M is a three-manifold and (H_1, H_2) is a Heegaard splitting of M , then $e(M) \geq e(H_1) + e(H_2) - e(H_1 \cap H_2) = e(H_1 \cap H_2)$. Specifically, if F is a splitting surface associated to a Heegaard splitting of \cdot ³, then F has one end.

Let (M, F_1, F_2) be a three-manifold with a hollow Heegaard splitting (H_1, H_2) , and let F be the splitting surface associated with the Heegaard splitting. It is a consequence of Haken's lemma for hollow Heegaard splittings [2, 4] that if there is

an incompressible sphere S in M , then there is an incompressible sphere S' in M that intersects F in a single simple closed curve. The proof of this theorem is no different from the proof in the case where we require that all the manifolds involved be compact; the compactness of the sphere S is all that is really necessary.

Let B denote the closed three-ball. Up to homeomorphism of B , there is a unique compact genus-one surface T with one boundary component, properly embedded in B so that there exist disks D_1 and D_2 embedded in B with $\partial D_i = D_i \cap T$ and such that $D_1 \cap D_2$ consists of a single point of transverse intersection of ∂D_1 and ∂D_2 in T . The surface T is the splitting surface associated to the unique (up to homeomorphism) genus-one Heegaard splitting with boundary of B having a single boundary component. The surface T is pictured in Figure 3.

Figure 3: The surface T inside the ball B

There is an operation on Heegaard splittings called stabilization. Let F be the splitting surface associated to a Heegaard splitting of the three-manifold M . Let B be a ball embedded in M that intersects F in a single disk D . Let F' be a surface obtained from F by removing the disk D and replacing it with a surface T as above. The surface F' is the splitting surface associated with a new Heegaard splitting (H'_1, H'_2) of M . We call the new Heegaard splitting the result of *stabilizing* the old Heegaard splitting. This operation is uniquely defined up to homeomorphism. It is a theorem of Reidemeister and Singer [29] that any two Heegaard splittings of

a closed three-manifold M become topologically equivalent after each is stabilized a finite number of times.

We would now like to discuss some topological uniqueness results of Waldhausen; these results are all consequences of his proof of the topological uniqueness of Heegaard splittings of the three-sphere [30]. Let M be a compact three-manifold with boundary that is the result of removing open balls from S^3 . Let F_1 and F_2 be surfaces in ∂M , so that $F_1 \cup F_2 = \partial M$, $F_1 \cap F_2 = \partial F_1 = \partial F_2$, and the intersection of F_i with any boundary component of M consists of a single disk. Any planar surface P that is properly embedded in M so that $\partial P = \partial F_1$ is the splitting surface associated with a Heegaard splitting with boundary of (M, F_1, F_2) . Furthermore, a simple argument shows that any two such splittings are topologically equivalent. It is a consequence of Waldhausen's theorem that any other Heegaard splitting with boundary of (M, F_1, F_2) is topologically equivalent to the result of stabilizing P the correct number of times. Specifically, Heegaard splittings of (M, F_1, F_2) are classified by their genus.

Assume that M has one end. Let (H_1, H_2) be a Heegaard splitting of M with splitting surface F . We say that (H_1, H_2) is *infinitely reducible* if there exists a proper family of disjoint balls $\{B_i\}_{i=1}^\infty$ in M so that each B_i intersects F in a copy of the surface T from Figure 3. We call the balls B_i *reducing balls*. The appellation comes from the fact that if we replace the surfaces $B_i \cap F$ with disks the resulting surface is still a Heegaard surface. If a Heegaard splitting is infinitely reducible then we have a great deal of latitude in arranging its intersection with compact submanifolds of M .

Proposition 2.1 *Suppose M has one end. Let (H_1, H_2) and (H'_1, H'_2) be infinitely reducible Heegaard splittings of (M, F_1, F_2) with splitting surfaces F and F' respectively. Suppose that K is a compact codimension 0 submanifold of its boundary. Suppose that G_1, G_2 is a partition of the boundary of K so that $F \cap K$ and $F' \cap K$ are splitting surfaces for (K, G_1, G_2) . Note that $F \cap \partial K = F' \cap \partial K = \partial G_1$. Then there are surfaces Φ and Φ' isotopic to F and F' with $\Phi \cap K = \Phi' \cap K$ the splitting surface of a Heegaard splitting of (K, G_1, G_2) .*

Proof. The proof is achieved by a process we call “stealing handles from infinity”. If we can show that we can isotopy F to a surface Φ so that $\Phi \cap \partial K = F \cap \partial K$ and $\Phi \cap K$ is the result of stabilizing $F \cap K$ an arbitrary number of times, then the Reidemeister-Singer theorem will imply the desired result.

Since K is compact there exist infinitely many reducing balls for (H_1, H_2) that are disjoint from K . Let B be such. Since a ball is a regular neighborhood of any point

in its interior we may isotope B so that it is a small ball centered at a point p in F . Let q be a point in $F \cap \overset{\circ}{K}$. Since F is path connected there is an arc in F joining p and q . Effect an isotopy supported in a small regular neighborhood of this arc that drags the contents of B to a small ball in $\overset{\circ}{K}$ centered at q . Call the resulting surface Φ . It is clear that we can effect this isotopy so that $\Phi \cap K$ is the result of stabilizing $F \cap K$ once, with $\Phi \cap \partial K = F \cap \partial K$. Furthermore we can repeat this process an arbitrary number of times. \square

Given a Heegaard splitting of a noncompact manifold we can find an exhaustion of the manifold by compact submanifolds so that the intersection of the Heegaard splitting with the compact “pieces” is a Heegaard splitting.

Proposition 2.2 *Let (H_1, H_2) be a Heegaard splitting of (M, F_1, F_2) with splitting surface F . There exists an exhaustion of M by compact submanifolds $K_i, K_0 = \emptyset, K_i \subseteq \overset{\circ}{K}_{i+1}$ so that for all i , $(H_1 \cap (K_i - \overset{\circ}{K}_{i-1}), H_2 \cap (K_i - \overset{\circ}{K}_{i-1}))$ is a Heegaard splitting of $K_i - \overset{\circ}{K}_{i-1}$ (with the obvious partition of $\partial(K_i - \overset{\circ}{K}_{i-1})$).*

Proof. Since H_1 is compression body with preferred surface F we can find an exhaustion L_i of H_1 by compact submanifolds so that for all i $L_i - \overset{\circ}{L}_{i-1}$ is a compression body with preferred surface $F \cap (L_i - \overset{\circ}{L}_{i-1})$. Similarly we can find an exhaustion J_i of H_2 so that the $J_i - \overset{\circ}{J}_{i-1}$ are compression bodies with preferred surface $F \cap (J_i - \overset{\circ}{J}_{i-1})$. Let K_i be the union of J_i and L_i along with collars of $J_i - L_i$ in H_1 and $L_i - J_i$ in H_2 , chosen to intersect $J_i \cup L_i$ nicely. The exhaustion K_i will have the desired property. \square

We call an exhaustion as above *adapted* to (H_1, H_2) .

Proposition 2.3 *If (H_1, H_2) and (H'_1, H'_2) are infinitely reducible Heegaard splittings of (M, F_1, F_2) with splitting surfaces F and F' then there exists an exhaustion $\{L_i\}$ of M so that after isotopies fixing ∂M , $\{L_i\}$ is adapted to both (H_1, H_2) and (H'_1, H'_2) and the intersections of F and F' with the frontier of each L_i coincide.*

Proof. Suppose that $\{K_i\}$ and $\{K'_i\}$ are exhaustions of M that are adapted to (H_1, H_2) and (H'_1, H'_2) . By inductively selecting subsequences and renumbering we may assume that for all i ,

$$K_{i-1} \subseteq \overset{\circ'}{K}_{i-1} \subseteq K'_{i-1} \subseteq \overset{\circ}{K}_i .$$

Choose the exhaustion L_i so that

$$K_{i-1} \subseteq \overset{\circ}{L}_i \subseteq L_i \subseteq K_i$$

and

$$K'_{i-1} \subseteq \overset{\circ}{L}_i \subseteq L_i \subseteq K'_i.$$

For instance the frontier of L_i could be a pushoff of the frontier of K_i into K_i . Partition the boundary of L_i into $(G_1(i), G_2(i))$ so that it coincides with F_1, F_2 on the overlap. There exist Heegaard splittings of $L_i - \overset{\circ}{K}_{i-1}$ and $K_i - \overset{\circ}{L}_i$ so that the partition of the boundary restricted to the boundary of L_i coincides with $(G_1(i), G_2(i))$ and the partition of the boundary restricted to the boundary of K_i coincides with the partition of the boundary of K_i induced by (H_1, H_2) . Together these Heegaard splittings form a Heegaard splitting of $K_i - \overset{\circ}{K}_{i-1}$ intersecting the boundary of L_i in $\partial G_1(i)$. We can stabilize $F \cap K_i - \overset{\circ}{K}_{i-1}$ so that it is isotopic relative to its boundary to a surface having $\partial G_1(i)$ as its intersection with the boundary of L_i . By stealing handles from infinity we can isotope F so that this is true. Still working with $(G_1(i), G_2(i))$ we can do the same with F' , that is after an isotopy F' intersects the boundary of L' in $\partial G_1(i)$. Furthermore we can do this so that $F \cap (K_i - \overset{\circ}{L}_i), F \cap (L_i - \overset{\circ}{K}_{i-1}), F' \cap (K'_i - \overset{\circ}{L}_i)$ and $F' \cap (L_i - \overset{\circ}{K}_{i-1})$ are all splitting surfaces. This means that $F \cap (L_i - \overset{\circ}{L}_{i-1})$ and $F' \cap (L_i - \overset{\circ}{L}_{i-1})$ are splitting surfaces and $F \cap \partial L_i = F' \cap \partial L_i$. Proceed inductively making sure that after some N , depending on i if $n \geq N$ then the surface's intersection with L_i is the same before and after the isotopies. This will imply that the process converges. \square

Theorem 2.1 *Let (H_1, H_2) and (H'_1, H'_2) be infinitely reducible Heegaard splittings of (M, F_1, F_2) with splitting surfaces F and F' . Then F and F' are isotopic.*

Proof. First apply Proposition 2.3 to find an exhaustion $\{L_i\}$ and isotopies of F and F' so that $\{L_i\}$ is adapted to the isotoped Heegaard splittings. Then use Proposition 2.1 inductively on $L_i - \overset{\circ}{L}_i$ to isotope F so that it coincides with F' . We can use the fact that all the handles we are stealing from infinity can be taken from the only end representative to make sure that after some stage in the construction we are not disturbing $L_j \cap F$. Hence the process converges. \square

It is clear that Theorem 1.2 from the introduction follows from Theorem 2.1.

3 Topological uniqueness of one-ended complete minimal surfaces

In this section we will be studying the geometry and topology of the closure of the components of the complement of properly embedded surfaces in \mathbb{R}^3 . These manifolds with boundary are almost-complete in the following sense.

Definition 3.1 *A Riemannian n -manifold with boundary is called almost-complete if it is complete as a metric space with respect to the natural distance function induced from the infimum the lengths of curves joining pairs of points in the manifold.*

We will study the topology of a properly embedded minimal surface M in \mathbb{R}^3 by showing that the closure of each component of $\mathbb{R}^3 - M$ is a standard one-ended handlebody whenever M has one end. When M has finite topology, this was proved by Meeks [18]; the case of interest here will be when M has one end and infinite genus.

Recall that a noncompact surface Σ in a Riemannian manifold N has *least area* if for any smooth compact subdomain $\Delta \subset \Sigma$, Δ is a surface of least area in N with boundary $\partial\Delta$.

Lemma 3.1 *Suppose N is a connected, orientable, almost-complete Riemannian three-manifold with more than one boundary component. If ∂N has nonnegative mean curvature with respect to the outward pointing normal, then N contains a properly embedded, orientable, least-area minimal surface.*

Proof. Suppose ∂_1 and ∂_2 are two components of ∂M . Choose an arc δ in N that joins a point $p \in \partial_1$ with a point of ∂_2 . Let $\tilde{\Sigma}_1 \subset \tilde{\Sigma}_2 \subset \dots$ be a smooth compact exhaustion of ∂_1 with $p \in \tilde{\Sigma}_1$. Theorem 1 in [23] (together with the general regularity theory of area-minimizing currents in [12] and [28]) shows that $\partial\tilde{\Sigma}_i$ is the boundary of a least-area surface Σ_i in N such that Σ_i is homologous *rel*(∂N) to $\tilde{\Sigma}_i$ with \mathbb{Z}_2 -coefficients. Note that Σ_i is orientable since $\Sigma_i \cup \tilde{\Sigma}_i$ is a boundary in N .

Since the surface Σ_i is area-minimizing in the interior of N , for any ball $B \subset \text{Int}(N)$, a simple replacement argument using portions of ∂B shows that $\text{Area}(B \cap \Sigma_i) \leq \frac{1}{2}\text{Area}(\partial B)$. Similarly, if B is a smooth ball of geodesic radius ε centered at a point in ∂N , then $\text{Area}(B \cap \Sigma_i) \leq \text{Area}(\partial B)$. These estimates show that the family $\{\Sigma_i\}$ has uniform local area bounds. These area bounds are sufficient for applying the standard compactness and regularity theorems [28] of geometric measure theory which state that a subsequence Σ_{i_j} of these surfaces converges smoothly on compact subsets of N to a properly embedded least-area surface Δ . (The property that a limit of area-minimizing surfaces is itself area-minimizing is well known and is proved in a similar context in the last paragraph of the proof of Theorem 3.1 in [24].) Note that each of the surfaces Σ_i has odd intersection number with the arc δ and so $\Delta \cap \delta \neq \emptyset$, which implies Δ is nonempty. This completes the proof of the lemma. \square

Theorem 3.1 *Suppose N is a connected, orientable, almost-complete, flat three-manifold. If ∂N has nonnegative mean curvature with respect to the outward pointing normal, then either ∂N is connected or N is isometric to the Riemannian product $\Sigma \times [0, T]$ for some $T > 0$ and for some complete totally geodesic surface Σ in N .*

Proof. Suppose N has at least two boundary components. For the moment, also assume that N is simply connected. We shall prove the N is isometric to $\mathbb{R}^2 \times [0, T]$ for some $T > 0$.

Let $M \subset N$ denote a properly embedded, stable, orientable, minimal surface whose existence is guaranteed in Lemma 3.1. By the work of do Carmo and Peng [5] or of Fischer-Colbrie and Schoen [7], we know that M is totally geodesic. Since N is simply connected, M must be a plane in N . (When N is simply connected, it isometrically submerses into \mathbb{R}^3 and so M must be a plane.) After a translation of M in N , we may assume that the distance from M to ∂N is zero. By the maximum principle, either $M \subset \partial N$ or else $M \cap \partial N = \emptyset$. Suppose for the moment that $M \cap \partial N = \emptyset$ and $\text{dist}(M, \partial N) = 0$ and identify M with the plane \mathbb{R}^2 .

Let D_t be the disk of radius t in \mathbb{R}^2 centered at the origin. Suppose $\text{dist}(D_1, \partial N) > \varepsilon$ and choose $\varepsilon < \frac{1}{4}$. Let γ denote the circle of height ε over ∂D_1 . The curves $\gamma \cup \partial D_1$ bound a stable catenoid C_1 with $C_1 \cap \partial N = \partial D_1$. (In our discussion of catenoids we are using the fact that some neighborhood of M in N isometrically embeds in \mathbb{R}^3 .) Furthermore it is clear that for t close to 1, $\gamma \cup \partial D_t$ is also the boundary of a stable catenoid C_t and the family C_t varies continuously with t . The maximum principle shows that the interiors of the one-parameter family of stable catenoids C_t are always disjoint from ∂N for $t \geq 1$ and for as long as C_t is defined in N . It is clear that C_t is defined for all $t \geq 1$ and C_{t_1} lies above C_{t_2} when $t_1 > t_2$. Since the C_t are stable catenoids, they converge to a totally geodesic surface C in N with $\partial C = \gamma$.

Figure 4:

Let E be the flat disk with $\partial E = \gamma$. Then $C_t \cup E \cup D_t$ bounds a compact region $R \subset N$. The regions R_t converge to a slab of width ε that is isometrically embedded in N and one of its boundary planes is M . These same arguments show that M is also the boundary of another slab of width ε on its other side. Hence, the distance from M to ∂N is positive, a contradiction of our earlier assumption that $M \cap \partial N = \emptyset$ and $\text{dist}(M, \partial N) = 0$.

If $M \subset \partial N$, a simple modification of the arguments given above in the case $M \cap \partial N = \emptyset$ shows that the boundary component M can be continuously translated away from itself until it touches another boundary component of N at which point it equals that boundary component. Thus, we see that N is isometric to $\mathbb{R}^2 \times [0, T]$ for some $T > 0$.

If N is not simply connected, then by the previously considered case, the simply connected Riemannian cover of N is isometric to $\mathbb{R}^2 \times [0, T]$ for some $T > 0$. Since the covering transformations are isometries and N has more than one end, N must be isometric to $\Sigma \times [0, T]$ where Σ is a flat orientable surface. \square

Remark 3.1 The main idea in the proof of Theorem 3.1 (of using limits of catenoids) was first used by Hoffman and Meeks in the proof of their Halfspace Theorem that states that a proper nonplanar minimal surface in \mathbb{R}^3 that is contained in a halfspace is a plane. The Halfspace Theorem and Theorem 3.1 are examples of maximum principles at infinity for proper minimal surfaces in a flat three-manifolds. (See [20] for a useful and general version of this type of maximum principle.)

Corollary 3.1 *Suppose N is an almost-complete flat three-manifold whose boundary has nonnegative mean curvature with respect to the outward pointing unit normal. If the map $\pi_1(\partial N) \rightarrow \pi_1(N)$ is not surjective, then N or a 2-sheeted covering space of N is a Riemannian product.*

Proof. If $\pi_1(\partial N) \rightarrow \pi_1(N)$ is not surjective, then the universal cover \widetilde{N} satisfies the hypotheses of Theorem 3.1 and $\partial \widetilde{N}$ is not connected. Hence, \widetilde{N} is isometric to $\mathbb{R}^2 \times [0, T]$ for some $T > 0$. The corollary follows immediately from this fact. \square

Corollary 3.2 *Suppose M is a properly embedded minimal surface in \mathbb{R}^3 and N is the closure of a component of $\mathbb{R}^3 - M$. Then the interior of N is an open handlebody and the induced map $\pi_1(M) \rightarrow \pi_1(N)$ is surjective.*

Proof. It follows from Theorem 3 in [18] that $\text{Int}(N)$ is an open handlebody. The second statement follows immediately from Corollary 3.1. \square

Remark 3.2 Corollary 3.2 was independently proved by Joel Hass (personal communication).

When a properly embedded minimal surface $M \subset \mathbb{R}^3$ has one end, we can prove even more concerning the topology of the closed complements of M .

Theorem 3.2 *Suppose M is a properly embedded one-ended minimal surface in \mathbb{R}^3 and N is the closure of one of the components of $\mathbb{R}^3 - M$. Then N is a one-ended handlebody. In particular, M is a Heegaard surface in \mathbb{R}^3 .*

The next theorem, which is stated in the Introduction, is a simple consequence of the above theorem and Theorem 1.2.

Theorem 1.1 *Two properly embedded one-ended minimal surfaces in \mathbb{R}^3 of the same genus are ambiently isotopic.*

Proof of Theorem 3.2. Let $M \subset \mathbb{R}^3$ be a properly embedded minimal surface with one end. If M has finite genus, then it was proved in [18] that M is a Heegaard surface. Assume now that M has infinite genus. We shall show that the closure N of a component of $\mathbb{R}^3 - M$ must be a handlebody. This will imply M is a Heegaard surface in \mathbb{R}^3 and Theorem 3.2 will then follow from Theorem 1.2.

Since $\text{Int}(N)$ is an open handlebody by Corollary 3.2, to prove N is a handlebody it suffices to prove that there exists a proper standardizing sequence $\mathcal{D} = \{D_1, D_2, \dots\}$ in N satisfying,

1. For all k , $\partial D_k = D_k \cap N$ represents a homotopically nontrivial curve in N ;
2. D_k separates N into a compact component N_k and a noncompact component where $\bigcup_{i \leq k} D_i \subset N_k$;
3. $\bigcup_k N_k = N$.

The first step in the proof is to construct an infinite sequence of auxiliary minimal surfaces $\{\Sigma_1, \Sigma_2, \dots\}$ that satisfy some of the properties required for the disks in \mathcal{D} . First choose a compact exhaustion $\tilde{\Sigma}_1 \subset \tilde{\Sigma}_2 \subset \dots$ of $M = \partial N$ where $\partial \tilde{\Sigma}_i$ is a simple closed curve. Since ∂N has nonnegative mean curvature and $\partial \tilde{\Sigma}$ bounds in N , $\partial \tilde{\Sigma}_i$ is the boundary of a compact least-area surface Σ_i in N homologous *rel*(∂N) to $\tilde{\Sigma}_i$ with \mathbb{Z}_2 -coefficients (see Theorem 1 in [23] and also [28]). Note Σ_i is orientable since $\Sigma_i \cup \tilde{\Sigma}_i$ bounds.

We next show that the Σ_i can be chosen so that $\bigcup_i \Sigma_i$ is a properly embedded submanifold of \mathbb{R}^3 . If the sequence Σ_i is not eventually disjoint from every compact subset of \mathbb{R}^3 , then, after choosing a subsequence, there exist points $p_i \in \Sigma_i$ with $p_i \rightarrow p$ for some point $p \in N$. Since Σ_i is a \mathbb{R}^2 -area-minimizing surface, a subsequence Σ_{i_j} of these surfaces converge smoothly on compact subsets of N to a properly embedded least-area surface Δ (see the proof of Lemma 3.1 for this convergence argument). Note that Δ is nonempty since $p \in \Delta$. But Δ is a complete stable orientable minimal surface in \mathbb{R}^3 and hence every component of Δ is a plane ([5] or [7]). The Halfspace Theorem in [16] states that a properly immersed minimal surface in \mathbb{R}^3 that is contained in halfspace is a plane but M is not a plane. This contradiction shows that the sequence Σ_i eventually leaves every compact subset of \mathbb{R}^3 . It follows, by choosing a subsequence, that we can also choose $\{\Sigma_i\}$ so that these surfaces are pairwise disjoint. This completes the construction of the family $\{\Sigma_i\}$.

Let R_i denote the noncompact region of N bounded by $\Sigma_i \cup (M - \tilde{\Sigma}_i)$. Note that $R_{i+1} \subset R_i$. We will construct the required sequence of disks \mathcal{D} by showing that for each i , there exists a disk $D_i \subset R_i$ with $\partial D_i = (D_i \cap \partial R_i) \subset M$ and such that ∂D_i is homologous in $\overline{M - \tilde{\Sigma}_i}$ to the curve $\partial \Sigma_i$. It is straightforward to check that such a collection of disks contains a reindexed subcollection with the required Properties 1–3 for the collection \mathcal{D} . We first prove the existence of the disk D_1 .

The two curves $\partial \Sigma_1 \cup \partial \Sigma_i$ bound a subdomain M_i of M . If either $\partial \Sigma_1$ or $\partial \Sigma_i$ is homotopically trivial in R_1 , then Dehn's Lemma [13] shows that this curve is the boundary of an embedded disk D_1 in R_1 . Hence, we may assume that $\partial \Sigma_1$ and $\partial \Sigma_i$ are both homotopically nontrivial in R_1 . The loop theorem [13] implies that there exists a pairwise disjoint collection of disks in R_1 with boundary curves in M_i such that after performing a surgery of M_i along these disks the resulting surgered surface \widehat{M}_i is incompressible in R_1 . (Recall that performing a surgery of M along a disk E with $\partial E \subset M$ means that for some product neighborhood, $P(E) \subset R_1$, we replace $P(E) \cap M$ by the two disks $\partial P(E) - (P(E) \cap M)$). Let M'_i denote the component of \widehat{M}_i that contains $\partial \Sigma_1$. Suppose for the moment that $\partial \Sigma_i \not\subset \partial M'_i$ for some i . In this case let D_1 be the boundary connected sum of the disks $M'_i \cap \text{Int}(N)$ along pairwise disjoint arcs in $M'_i \cap M_i$. Note that D_1 is homologous *rel*($\partial R_1 - \text{Int}(\Sigma_1)$) in R_1 to Σ_1 . Hence, we may assume that the incompressible surface M'_i has boundary $\partial \Sigma_1 \cup \partial \Sigma_i$.

Replace the incompressible surface M'_i by an embedded minimal surface \widetilde{M}_i of least area in R_1 in the isotopy (or homotopy class) of M'_i (see [8] or [21]). We will prove in Assertion 3.1 that a subsequence \widetilde{M}_{i_j} of the \widetilde{M}_i converges smoothly on compact subsets of \mathbb{R}^3 to a smooth, connected, noncompact, properly embedded,

stable, orientable, minimal surface $\Sigma \subset R_1$ with $\partial\Sigma = \partial\Sigma_1$. Assume for the moment that Assertion 3.1 holds and Σ is given.

We first check that Σ is incompressible. Let α be a simple closed curve in Σ that bounds a disk D in R_1 . Since \widetilde{M}_{i_j} converges smoothly to Σ on compact subsets of R_1 , for j large we can lift α to a nearby $\alpha_j \subset \widetilde{M}_{i_j}$ and α_j is homotopically trivial in R_1 . Since \widetilde{M}_{i_j} is incompressible, α_j is the boundary of a minimal disk $D_j \subset \widetilde{M}_{i_j}$ contained in the convex hull of α_j . Note however that a subsequence of the least-area minimal disks $\{D_j\}$ converges to a least-area disk $D' \subset \Sigma$ with $\alpha = \partial D'$ (see [22] for this type of compactness argument). This proves Σ is incompressible.

It follows from [6] (or Theorem 2.1 in [24]) that Σ has finite total curvature (since Σ is complete, orientable, stable and $\partial\Sigma$ is compact) and hence, Σ has finite topology. Since Σ has finite genus and ∂R_1 has infinite genus we conclude that $\Sigma \not\subset \partial R_1$. The maximum principle implies $\Sigma \cap \partial R_1 = \partial\Sigma$. Since Σ has finite total curvature, its ends are asymptotic to planes and catenoids (see [26]). Let $B(r)$ denote the ball of radius r centered at the origin. For large values of r , the sphere $\partial B(r)$ intersects Σ almost orthogonally in a finite collection of curves that are geometrically close to a fixed great circle. In particular, for some fixed large value of r , Σ separates $\mathbb{R}^3 - B(r)$ into a finite number of components, exactly one of which contains the end of $M \cap (\mathbb{R}^3 - B(r))$. Since M has one end, $M \cap (\overline{\mathbb{R}^3 - B(r)})$ has exactly one noncompact component, and therefore the convex hull property implies that $M \cap (\mathbb{R}^3 - B(r))$ is connected. Hence, every component δ of $\Sigma \cap \partial B(r)$ bounds a disk in $\partial B(r)$ that is disjoint from M and therefore this disk is contained in R_1 . But δ is homotopically nontrivial on Σ and Σ is incompressible in R_1 . This contradiction proves the existence of D_1 .

Replacing Σ_1 with Σ_i and repeating the above argument proves the existence of a disk $D_i \subset R_i$ that is homologous to Σ_i in $R_i \text{ rel}(\partial R_i - \text{Int}(\Sigma_i))$. It is straightforward to prove that the disks $\{D_i\}$ have the required properties, which completes the proof of the existence of the family \mathcal{D} . Thus, to complete the proof of Theorem 3.2, it remains only to prove the next assertion.

Assertion 3.1 *A subsequence \widetilde{M}_{i_j} of the surfaces \widetilde{M}_i converges smoothly on compact subsets of \mathbb{R}^3 to a smooth, connected, noncompact, properly embedded, stable, orientable, minimal surface $\Sigma \subset R_1$ with $\partial\Sigma = \gamma = \partial\Sigma_1$.*

Proof of Assertion 3.1. Suppose a subsequence \widetilde{M}_{i_j} converges smoothly to a properly embedded minimal surface Σ with boundary γ . Then each component of Σ is a properly embedded stable minimal surface. If Σ is not connected, then there is a component Δ of Σ that is a properly embedded surface in \mathbb{R}^3 and has empty boundary. Since Δ separates \mathbb{R}^3 , it is *orientable*. If Δ is unstable, then it contains a smooth

compact subdomain $\tilde{\Delta}$ that is unstable. Since there are subdomains $\tilde{\Delta}(i_j) \subset \tilde{M}_{i_j}$ that converge smoothly to $\tilde{\Delta}$, the lowest eigenvalue of the Jacobi operators on $\tilde{\Delta}(i_j)$ converge to the lowest eigenvalue of the Jacobi operator on $\tilde{\Delta}$, which is negative. This implies $\tilde{\Delta}(i_j)$ is unstable for j large, which contradicts the stability of \tilde{M}_{i_j} . Therefore Δ is stable. But a complete stable orientable surface Δ is a plane [5, 7] and so M lies in a halfspace. By the Halfspace Theorem [16], M must be a plane, which gives a contradiction. This contradiction proves Σ is *connected* and, as we showed for Δ above, Σ is *stable*. Since the boundary sphere of any ball $B(r)$ containing γ in its interior must intersect \tilde{M}_{i_j} for all j sufficiently large, Σ must intersect $\partial B(r)$. This implies that Σ is *noncompact*. If $\Sigma \cap \partial R_1 \neq \gamma$, then the maximum principle implies $\Sigma \subset \partial R_1$ and must equal $\overline{\partial R_1 - M_1}$ since Σ is noncompact. Hence $\Sigma \cup \Sigma_1$ is a properly embedded piecewise smooth surface in \mathbb{R}^3 and so Σ is *orientable*.

Thus, it suffices to prove that some subsequence \tilde{M}_{i_j} converges smoothly on compact subsets of \mathbb{R}^3 to a properly embedded minimal surface. To prove this it is sufficient to prove that *on compact balls B in \mathbb{R}^3 , the surfaces $\tilde{M}_i \cap B$ satisfy uniform curvature and area bounds*. Let $\beta(i)$ denote the other boundary curve $\partial \tilde{M}_i - \gamma$. Replace the surfaces \tilde{M}_{i_j} by smooth subdomains N_{i_j} , where N_{i_j} is obtained from \tilde{M}_{i_j} by removing a smooth open subdomain of points in \tilde{M}_{i_j} of intrinsic distance approximately 1 from $\beta(i)$. Our first step in proving the existence of a convergent subsequence is to derive *uniform curvature estimates* for the family $\{N_{i_j}\}$ in *all* of \mathbb{R}^3 .

Recall that Schoen [25] proved that there is a universal constant c such that the Gaussian curvature K on \tilde{M}_i satisfies

$$|K(p)| \leq \frac{c}{(d(p))^2},$$

where $d(p)$ is the intrinsic distance of p to $\partial \tilde{M}_i$. Thus to derive our uniform curvature estimates it remains to prove that the Gaussian curvature of the surfaces $\{N_i\}$ is uniformly bounded on some intrinsic ε -neighborhood of γ , ε chosen independent of i .

Consider a small ε -neighborhood $F(\varepsilon)$ of γ in R_1 . There exists a small ε_0 such that for all positive $\delta < \varepsilon_0$, $A(\delta) = \partial F(\delta) - \partial R_1$ is an incompressible annulus in R_1 with nowhere zero mean curvature vectorfield pointing into $F(\delta)$ and the area of this annulus is at most $2\pi\delta L$ where L is the length of γ . ($A(\delta)$ is incompressible since γ is homotopically nontrivial in R_1 .) Fix such a number ε_0 .

We want to prove that there is a choice of $\delta < \varepsilon_0$ such that for all i , the component of $N_i \cap F(\delta)$ containing γ is an annulus. As a first step, we show that we can choose $\delta < \varepsilon_0$ so that every least-area disk $D \subset R_1$ with $\partial D \subset A(\delta)$ must be contained in $F(\delta)$. First suppose $D \subset F(\varepsilon_0)$. Then $D \subset F(\delta)$ by the maximum principle

(applied to the family of surfaces $A(t)$, $\delta \leq t \leq \varepsilon_0$). Suppose now that D contains points outside of $A(\varepsilon_0)$. Then it contains some point of distance $\varepsilon_0 - \delta$ from ∂D and hence, by the monotonicity formula, D has area at least $\pi(\varepsilon_0 - \delta)^2$. Since $A(\delta)$ is incompressible in R_1 , ∂D bounds a disk in $A(\delta)$ of area less than $2\pi\delta L$. Therefore, if δ is chosen to satisfy $(\varepsilon_0 - \delta)^2 > 2\delta L$, then D does not have least area. This proves that $D \subset F(\varepsilon_0)$, after choosing δ so that $(\varepsilon_0 - \delta)^2 > 2\delta L$, and hence $D \subset F(\delta)$.

Since \widetilde{M}_i is transverse to $A(t)$ for almost all small t , we can choose δ so that $A(\delta)$ is also transverse to all the \widetilde{M}_i . Let $\Delta(i)$ be the component of $\widetilde{M}_i \cap F(\delta)$ containing γ . Elementary three-manifold topology shows $\Delta(i)$ is an annulus if and only if it is incompressible in $F(\delta)$, since $\pi_1(F(\delta)) = \mathbb{Z}$. Suppose $\Delta(i)$ is not incompressible in $F(\delta)$. Then there exists a homotopically nontrivial simple closed curve $\alpha(i)$ in $\Delta(i)$ that bounds a disk in $F(\delta)$. Since \widetilde{M}_i is incompressible and $\Delta(i) \subset \widetilde{M}_i$, there exists a disk $D(i) \subset \widetilde{M}_i$ with boundary $\alpha(i)$. By our choice of δ , $D(i) \subset F(\delta)$. This implies $D(i) \subset \Delta(i)$, which is impossible since $\Delta(i)$ is the component of $\widetilde{M}_i \cap F(\delta)$ containing γ . This contradiction proves there exists a δ such that $\Delta(i)$ is an annulus.

The areas of the least-area annuli $\Delta(i)$ are bounded by the sum of the areas of $A(\delta)$ and the area of $F(\delta) \cap (\Sigma_1 \cup M)$, since $\partial\Delta(i)$ is the boundary of an annulus on this surface. This area bound implies that every subsequence $\Delta(i_j)$ contains a subsequence that converges smoothly in $F(\delta) - (\gamma \cup A(\delta))$. (See the proof of Theorem 2 in [22] for details on this convergence property). Hildebrandt's boundary regularity theorem [14] states that such a least-area limit annulus is smooth along γ . A well-known consequence of Hildebrandt's proof of boundary regularity is that when a sequence $\{E(i)\}$ of smooth minimal surfaces converges to a smooth minimal surface E and a component $\partial(i)$ of $\partial E(i)$ converges smoothly to a component ∂ of ∂M , then the convergence of these surfaces is smooth near ∂ . Therefore, every subsequence $\Delta(i_j)$ contains a subsequence that converges smoothly in $F(\delta) - A(\delta)$ and this convergence is smooth along γ . Since every subsequence of the $\Delta(i)$ has a smoothly converging subsequence, the curvatures of all the $\Delta(i)$ are uniformly bounded. This completes the proof that the curvature of the family $\{N_i\}$ is uniformly bounded in \mathbb{R}^3 .

Suppose F is a compact surface in \mathbb{R}^3 satisfying

1. F has one boundary component Γ in $B(r_1)$ and the rest of its boundary components outside of the ball $B(r_2)$ where $r_2 > r_1$.
2. The curvature of Γ is bounded by a constant C_1 .
3. The length of Γ is bounded by a constant C_2 .
4. The Gaussian curvature of F is bounded from below by a constant C_3 .

Let $E(t)$ be the area of the subdomain $F(t)$ of F of intrinsic distance t from Γ for $t < (r_2 - r_1)$. By comparison formulas with surfaces of constant Gaussian curvature C_3 , there exist constants K_1, K_2 that depend on C_1, C_2, C_3 such that $E(t) \leq K_1 + K_2^t$.

Suppose $\gamma \subset B(r_1)$. After discarding some of the surfaces N_i and reordering, we may assume that the other boundary curves of N_i lie outside $B(i)$. Then the above area estimate implies that the area $E(i, t)$ of the subdomain of intrinsic distance t from γ satisfies $E(i, t) \leq K_1 + K_2^t$ for $t < i - r_1$, where K_1, K_2 depend on γ and the earlier obtained uniform curvature estimate for $\{N_i\}$.

Suppose now that the areas of the family are not uniformly bounded on some large ball B . Since $E(i, t) \leq K_1 + K_2^t$, for $t < i - r_1$, there is a point $p \in B$ and a sequence of points $p(i_j) \in N_{i_j}$ converging to p and such that $\text{dist}(p(i_j), \partial N_{i_j}) \rightarrow \infty$ as $j \rightarrow \infty$, where dist is the intrinsic distance. By Schoen's curvature estimates [25], the surfaces N_{i_j} are getting flatter and flatter in larger and larger disk regions $D(i_j)$ centered at $p(i_j)$ as $j \rightarrow \infty$. Hence, a subsequence of the $D(i_j)$ converges to a flat plane $P \subset R_1$ passing through p . By the Halfspace Theorem [16], M must be a plane. This contradiction completes the proof of Assertion 3.1, which in turn completes the proof of Theorem 3.2. \square

4 Examples and counterexamples

We first describe three important classical examples of properly embedded minimal surfaces with one end and infinite genus. The first example is the triply-periodic minimal surface pictured in Image 1. It is called the Schwarz Primitive surface and was discovered independently by Schwarz and Riemann. In Images 2 and 3 appear two well-known examples of Scherk, one that is doubly-periodic and the other that is one-periodic. Scherk's doubly-periodic example is asymptotic in \mathbb{R}^3 , as $x_3 \rightarrow +\infty$, to the planes $P_i = \{(t, i, s) \mid t, s \in \mathbb{R}\}$ for $i \in \mathbb{Z}$ and asymptotic, as $x_3 \rightarrow -\infty$, to the planes $Q_i = \{(i, t, s) \mid t, s \in \mathbb{R}\}$ for $i \in \mathbb{Z}$. Scherk's one-periodic surface is asymptotic, away from the x_2 -axis, to the union of two orthogonal planes containing the x_2 -axis.

Image 1: Schwarz's Primitive Surface

Image 2: Scherk's Doubly Periodic Surface

Image 3: Scherk's Singly Periodic Surface

Let $k \subseteq S^3$ be the Artin-Fox curve. Let $k' \subset \mathbb{R}^3$ be the curve obtained by removing the wild point of the Artin-Fox curve from k and S^3 . Let F be the boundary of a regular neighborhood of k' . The closure of the component of the complement of F that corresponds to the exterior of the regular neighborhood is a fake halfspace. Choose an infinite family of disks in F that form a proper family. Replace each disk by an unknotted handle. The resulting surface F' , pictured below, is not a Heegaard surface. In this case it is possible to construct a *nonproper* standardizing sequence of disks for the wild side of F , where the boundary curves of the disks are proper.

Figure 5:

An open handlebody is a three-manifold without boundary that is homeomorphic to an open regular neighborhood of some one-complex that is properly embedded in \mathbb{R}^3 . In [18] it is proved that if $F \subseteq \mathbb{R}^3$ is a properly embedded surface in \mathbb{R}^3 and there exists $p \in \mathbb{R}^3$ such that the distance from p on F induces a Morse function having only index one and index zero critical points, then the connected components of the complement of F in \mathbb{R}^3 are open handlebodies. This argument can be strengthened to show that if W is the closure of a component of the complement of F , then W can be embedded into a handlebody H so that the complement of the image of W in H is a closed subset of the boundary of H . However, this is not enough to prove that W is a handlebody. In the following figure we show a one-complex X embedded in \mathbb{R}^3 . Let F be the boundary of a regular neighborhood of X . Let W denote the closure of the component of the complement of F corresponding to the exterior of the regular neighborhood. Notice that if F was constructed carefully, then the distance from the point p induces a Morse function on F with exactly two index zero critical

points and no index two critical points. However, W is not a handlebody. In this case, $\pi_i(F) \rightarrow \pi_1(W)$ is injective (and surjective).
